

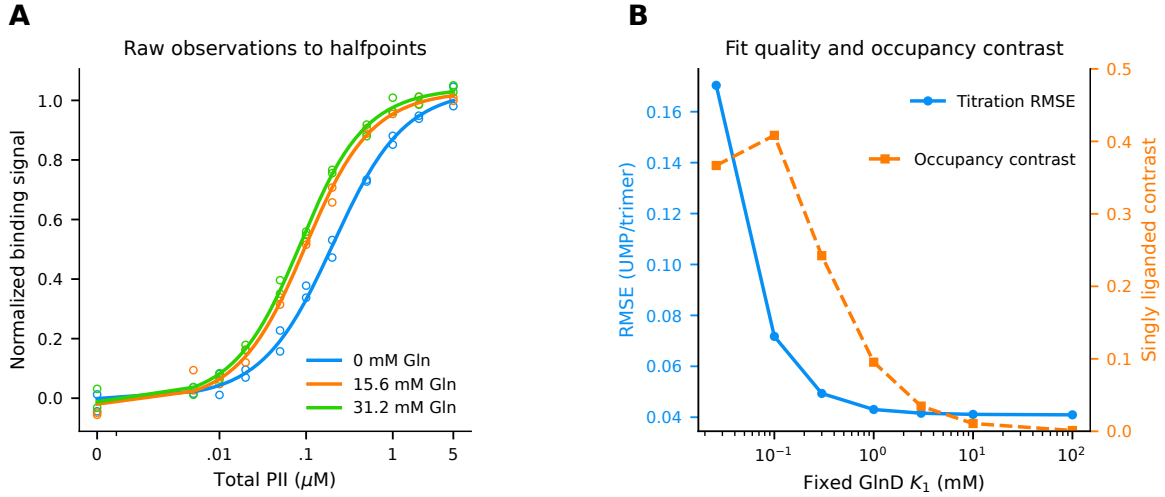

Figure S8: **Raw-assay fits and GlnD profiles retain different diagnostic roles.** (A) One simulated three-condition GlnE titration, with two readings at eleven doses. Lines show finite-depletion fits with separate background and gain for each glutamine condition. This synthetic example uses $\alpha_1 = 0.25$ and $K_G = 15.6$ mM; complete raw observations and fitted parameters are supplied in S1 Data. (B) GlnD fixed- K_1 profiles retaining two endpoint specificity ratios while releasing the fixed-capacity, intermediate-state and transported 0.080 mM UR half-range restrictions. Titration RMSE improves as the available singly liganded occupancy contrast shrinks. These profiles are cross-assay stress hypotheses, not confidence intervals or measured binding affinities.
